

CYP2D6: paroxetine

1563/1564/1565

AUC = area under the concentration-time curve, Cl_{or} = oral clearance, Css = steady state plasma concentration,= EM = extensive metaboliser (gene dose 1.5-2.5) (normal CYP2D6 enzyme activity), IM = intermediate metaboliser (gene dose 0.5-1) (reduced CYP2D6 enzyme activity), MADRS = Montgomery-Åsberg Depression Rating Scale, NS = non-significant, PM = poor metaboliser (gene dose 0) (absent CYP2D6 enzyme activity), S = significant, $t_{1/2}$ = half-life, SmPC = summary of product characteristics, UM = ultra-rapid metaboliser (gene dose \geq 3) (increased CYP2D6 enzyme activity), V_m = maximum elimination rate.

Disclaimer: The Pharmacogenetics Working Group of the KNMP formulates the optimal recommendations for each phenotype group based on the available evidence. If this optimal recommendation cannot be followed due to practical restrictions, e.g. therapeutic drug monitoring or a lower dose is not available, the health care professional should consider the next best option.

Brief summary and justification of choices:

CYP2D6 converts paroxetine to inactive metabolites. Paroxetine is a strong inhibitor of CYP2D6. As a result, the effect of CYP2D6 on the pharmacokinetics of paroxetine is greater for a single dose than for the repeated doses used in practice (the difference between EM and PM is reduced by a factor 3.5). There is no obvious relationship between the plasma concentration and the effect of paroxetine.

- IM and PM: The dose-corrected plasma concentration is increased for IM and PM. However, there is no effect on side effects or efficacy. Therefore, NO action is required for this gene-drug interaction (guideline without therapeutic recommendations).
- UM: For 71% of the UMs where the plasma concentration was determined (n=7), this value was below the detection limit following standard doses of paroxetine. There was no therapeutic efficacy in 100% of the UMs for who the therapeutic efficacy was determined (n=6). As a precaution, we recommend selecting an alternative (guideline with therapeutic recommendations).

You can find a detailed overview of the observed kinetic and clinical consequences per phenotype in the background information text of the gene-drug interactions on the KNMP Kennisbank. You might also have access to this background information text via your pharmacy or physician electronic decision support system.

Recommendation concerning pre-emptive genotyping, including justification of choices:

The Dutch Pharmacogenetics Working Group considers genotyping before starting paroxetine to be potentially beneficial for drug efficacy. Genotyping can be considered on an individual patient basis. If, however, the genotype is available, the Dutch Pharmacogenetics Working Group recommends adhering to the gene-drug guideline. The clinical implication of the gene-drug interaction scores 0 out of the maximum of 10 points (with pre-emptive genotyping considered to be potentially beneficial for scores ranging from 0 to 2 points) (see also the clinical implication score tables at the end of this risk analysis):

No severe clinical effects were observed in users of paroxetine with a variant phenotype. The maximum severity code was C corresponding to CTCAE grade 2. This results in a score of 0 out of the maximum of 2 points for the first criterion of the clinical implication score, the clinical effect associated with the gene-drug interaction (only points for CTCAE grade \geq 3).

The lack of a severe clinical effect also results in a score of 0 of the maximum of 3 points for the second and third criterion of the clinical implication score: the level of evidence supporting an associated clinical effect grade \geq 3 and the number needed to genotype (NNG) in the Dutch population to prevent one clinical effect code \geq D (grade \geq 3). The Summary of Product Characteristics (SmPC) of paroxetine does not mention a CYP2D6 genotype or phenotype and does not recommend pre-emptive genotyping. This results in 0 out of the maximum of 2 points for the fourth and last criterion of the clinical implication score, the pharmacogenetics information in the SmPC (only points for at least one genotype/phenotype mentioned in the SmPC or a recommendation to genotype).

The table below uses the KNMP nomenclature for EM, PM, IM and UM. As a result, the definitions of EM, PM, IM and UM in the table below can differ from the definitions used by the authors in the article.

Source	Code	Effect	Comments
ref. 1 Janssen PK et al. Nonresponders to daily paroxetine and another SSRI in men with lifelong premature ejaculation: a pharma- cokinetic dose-escala- tion study for a rare phenomenon. Korean J Urol 2014;55:599-607. PubMed PMID: 25237462.	3 IM: AA	 13 men with lifelong premature ejaculation, of which 5 did not respond to paroxetine and another SSRI and 1 did not respond to paroxetine, received paroxetine for 12 weeks (10 mg/day in weeks 1-4, 20 mg/day in weeks 5-8 and 30 mg/day in weeks 9-12). Co-medication was excluded. Genotyping: - 11x EM - 2x IM Results: IM versus EM: - no difference in intra-vaginal ejaculation latency time (NS) - higher plasma concentration with use of 30 mg/day (NS; significance could not be determined due to low number of patients) With each of the doses, there was no difference in the plasma concentration of paroxetine between responders (increase in the intra- vaginal ejaculation latency time by a factor 2 or more) and non-responders. NOTE: Genotyping was performed for *3, *4, *6 and gene duplication. 	Authors' conclusion: 'We did find that serum concentrations of paroxe- tine were higher in two men with the Cyp2D6*3 and *4 variations, respec- tively. However, because there is no relation between the serum paro- xetine concentration and the intravaginal ejaculatory latency time, this genotype for paroxetine metabolism is not relevant for paroxe- tine-induced ejaculation delay in the current study.'
ref. 2 Saruwatari J et al. Possible impact of the CYP2D6*10 polymor- phism on the nonlinear pharmacokinetic parameter estimates of paroxetine in Japanese patients with major depressive disorders. Pharmgenomics Pers Med 2014;7:121-7. Pubmed PMID: 24868171.	4 IM+EM : A	 and gene duplication. 15 patients were treated with paroxetine (20 mg/day during week 1, 40 mg/day during weeks 2-6, dose adjustment based on side effects) for at least 2 weeks. Relevant co-medication was excluded. Blood was collected 10-20 hours after the last dose (mean 13.5 hours). Carriers of the *10 allele were significantly younger than non-carriers (36.5 and 62.5 years respectively). Genotyping: 11x *10 (2x *2/*10, 2x *10/*39, 6x *10/*10, 1x *5/*10) 4x no *10 (2x *39/*39, 2x *5/*39) *10 versus (no *10): decrease in the dose-corrected plasma concentration determined using multiple linear regression (S) NOTE: The abovementioned contradicts the trend found with multiple linear regression for a decrease in the maximum conversion rate V_{max} (NS). no significant difference in plasma concentrations for patients who were treated with the same dose (20, 30 or 40 mg/day) Age was not included in the linear regression. However, age had no effect on V_{max}, either in *10 or in (no *10). NOTE: genotyping was performed for *2, *4, *5, *10, *18, *39 and *41. These are the most common variant alleles in this Japanese population group. 	Authors' conclusion: 'This is the first study to demonstrate that CYP2D6 *10 polymorphism could affect the nonlinear phar- macokinetic parameter estimates of paroxetine in Asian populations.'

Risk group UM with CYP2D6 inducer	
-----------------------------------	--

Comments: =

- Kinetic articles with single dosing were not included for the period after 2014. As paroxetine is a strong inhibitor of CYP2D6, kinetic data for single use provide too little information about the kinetics of repeated doses. In addition, after 2016 only kinetic articles providing the AUC of C_{ss} of paroxetine per CYP2D6 phenotype were included.
- Zourková A et al. Links among paroxetine-induced sexual dysfunctions, gender, and CYP2D6 activity. J Sex Marital Ther 2007;33:343-55:

One of the conclusions from this article is that the CYP2D6 genotype is a poor predictor of the CYP2D6 activity in long-term users of paroxetine (10-40 mg/day; average 23.2 mg/day). Of the 36 paroxetine users with genotype *1/*1 (screening for *3, *4, *5, *6 and gene duplication), 61% was phenotypically PM and only 39% was phenotypically EM[#] (EM+IM+UM) when phenotyping was performed using dextromethorphan. Of the 19 paroxetine users with gene dose 1 or 0, 74% was phenotypically PM and 26% was phenotypically EM[#].

Existing guidelines:

Hicks JK et al. Clinical Pharmacogenetics Implementation Consortium (CPIC) guideline for CYP2D6 and CYP2C19 genotypes and dosing of selective serotonin reuptake inhibitors. Clin Pharmacol Ther 2015;98: 127-34. PubMed PMID: 25974703.

CPIC uses the same definition for PM as we do. However, CPIC uses different definitions for EM (gene dose 1-2), IM (gene dose 0.5) and UM (gene dose \geq 2.5). The summary below uses the KNMP definitions for EM, PM, IM and UM.

CPIC indicates that gene dose \geq 2.5 results in low or undetectable plasma concentrations in comparison to gene dose 1-2 (Charlier 2003, Gex-Fabry 2008, Guzey 2006 and Lam 2002). Although the minimum therapeutic concentration of paroxetine has not been properly defined, low plasma concentrations can increase the risk of failure of the therapy. Therefore, for gene dose \geq 2.5, the CPIC recommends considering an alternative SSRI that is not primarily metabolised by CYP2D6. CPIC indicates that there are insufficient data to calculate an initial dose for gene dose \geq 2.5. CPIC classifies the recommendation for gene dose \geq 2.5 as "strong".

CPIC indicates that PM results in a significantly higher exposure to gene dose 1-2 (Charlier 2003 and Sawamura 2004). This higher exposure can be a risk factor for side effects. In order to prevent possible side effects, the CPIC recommends considering an alternative SSRI that is not primarily metabolised by CYP2D6. If treatment with paroxetine is desired, the CPIC recommends a dose reduction by 50%. The percentage dose reduction is derived from percentage differences in oral clearance calculated/estimated by Stingl JC et al. Mol Psychiatry 2013;18:273-87. As therapeutic drug monitoring is not commonly performed for SSRIs, there are only limited data available about a linear or non-linear correlation between dose and plasma concentration of paroxetine and the correlation between the plasma concentration and therapeutic effect and side effects. Therefore, the CPIC classifies the strength of the recommendation for PM as "optional".

According to CPIC, no action is required for gene dose 0.5. Although gene dose 0.5 probably results in a modest increase in exposure and an increased sensitivity to CYP2D6 inhibition, the existing evidence does not support adjustment of the therapy. CPIC classifies the recommendation to start the standard initial dose for gene dose 0.5 as "moderate". The reason for this is that the literature is difficult to assess, because of inconsistent categorisation of the genotypes into either the phenotype group IM or EM. However, CPIC classifies the recommendation to start the standard initial dose for gene dose 1-2 as "strong". The reasonmendations are as follows:

- gene dose \geq 2.5: consider an alternative that is not predominantly metabolised by CYP2D6.

- IM (gene dose 0.5 or 1): no action required.

PM: choose an alternative that is not predominantly metabolised by CYP2D6, or - if paroxetine is desired - consider decreasing the dose to 50% of the standard initial dose and adjust the dose based on effect.
 On 9-4-2018, there was not a more recent version of the recommendations present on the PharmGKB- and on the CPIC-site.

Date of literature search: 6 April 2018.

Mechanism:

Paroxetine is primarily metabolised by CYP2D6 to inactive metabolites. Paroxetine is a strong inhibitor of CYP2D6. As a result, the pharmacokinetics of paroxetine are non-linear (an increase in a dose of 20 mg/day by a factor 1.5 results in an increase in the paroxetine concentration by a factor 1.9) and the effect of CYP2D6 on the pharmacokinetics of paroxetine is greater for a single dose than for repeated doses (the difference between EM and PM is reduced by a factor 3.5).

Clinical Implication Score:

Table 1: Definitions of the available Clinical Implication Scores

Potentially beneficial	PGx testing for this gene-drug pair is potentially beneficial. Genotyping can be considered on an individual patient basis. If, however, the genotype is available, the DPWG recommends adhering to the gene-drug guideline	0-2 +
Beneficial	PGx testing for this gene-drug pair is beneficial. It is advised to genotype the patient before (or directly after) drug therapy has been initiated to guide drug and dose selection	3-5 +
Essential	PGx testing for this gene-drug pair is essential for drug safety or efficacy. Genotyping must be performed before drug therapy has been initiated to guide drug and dose selection	6-10 +

Table 2: Criteria on which the attribution of Clinical Implication Score is based

Clinical Implication Score Criteria	Possible Score	Given Score
Clinical effect associated with gene-drug interaction (drug- or diminished efficacy-induced))
